#### Abstract

We prove that every digraph has a vertex 4 -colouring such that for each vertex $v$, at most half the out-neighbours of $v$ receive the same colour as $v$. We then obtain several results related to the conjecture obtained by replacing 4 by 3 .

## 1 Introduction

A majority colouring of a digraph is a function that assigns each vertex $v$ a colour, such that at most half the out-neighbours of $v$ receive the same colour as $v$. In other words, at least half the out-neighbours of $v$ receive a colour different from $v$ (hence the name 'majority'). Whether every digraph has a majority colouring with a bounded number of colours was posed as an open problem on mathoverflow [10]. In response, Ilya Bogdanov proved that a bounded number of colours suffice for tournaments. The following is our main result.

Theorem 1. Every digraph has a majority 4-colouring.
Proof. Fix a vertex ordering. First, 2-colour the vertices left-to-right so that for each vertex $v$, at most half the out-neighbours of $v$ to the left of $v$ in the ordering receive the same colour as $v$. Second, 2-colour the vertices right-to-left so that for each vertex $v$, at most half the out-neighbours of $v$ to the right of $v$ in the ordering receive the same colour as $v$. The product colouring is a majority 4 -colouring.

[^0]Note that this proof implicitly uses two facts: (1) every digraph has an edge-partition into two acyclic subgraphs, and (2) every acyclic digraph has a majority 2 -colouring.

The following conjecture naturally arises:

## Conjecture 2. Every digraph has a majority 3-colouring.

This conjecture would be best possible. For example, a majority colouring of an odd directed cycle is proper (since each vertex has out-degree 1), and therefore three colours are necessary. There are examples with large minimum out-degree as well. For odd $k \geqslant 1$ and prime $n \gg k$, let $G$ be the directed graph with $V(G)=\left\{v_{0}, \ldots, v_{n-1}\right\}$ where $N_{G}^{+}\left(v_{i}\right)=\left\{v_{i+1}, \ldots, v_{i+k}\right\}$ and vertex indices are taken modulo $n$. Suppose that $G$ has a majority 2 -colouring. If some sequence $v_{i}, v_{i+1}, \ldots, v_{i+k}$ contains more than $\frac{k+1}{2}$ vertices of one colour, say red, and $v_{i}$ is the leftmost red vertex in this sequence, then more than $\frac{k-1}{2}$ out-neighbours of $v_{i}$ are red, which is not allowed. Thus each sequence $v_{i}, v_{i+1}, \ldots, v_{i+k}$ contains exactly $\frac{k+1}{2}$ vertices of each colour. This implies that $v_{i}$ and $v_{i+k+1}$ receive the same colour, as otherwise the sequence $v_{i+1}, \ldots, v_{i+k+1}$ would contain more than $\frac{k+1}{2}$ vertices of the colour assigned to $v_{i+k+1}$. For all vertices $v_{i}$ and $v_{j}$, if $\ell=\frac{j-i}{k+1}$ in the finite field $\mathbb{Z}_{n}$, then $j=i+\ell(k+1)$ and $v_{i}, v_{i+(k+1)}, v_{i+2(k+1)}, \ldots, v_{i+\ell(k+1)}=v_{j}$ all receive the same colour. Thus all the vertices receive the same colour, which is a contradiction. Hence the claimed 2-colouring does not exist.

Note that being majority $c$-colourable is not closed under taking induced subgraphs. For example, let $G$ be the digraph with $V(G)=\{a, b, c, d\}$ and $E(G)=\{a b, b c, c a, c d\}$. Then $G$ has a majority 2-colouring: colour $a$ and $c$ by 1 and colour $b$ and $d$ by 2. But the subdigraph induced by $\{a, b, c\}$ is a directed 3 -cycle, which has no majority 2 -colouring.

The remainder of the paper takes a probabilistic approach to Conjecture 2, proving several results that provide evidence for Conjecture 2. A probabilistic approach is reasonable, since in a random 3-colouring, one would expect that a third of the out-neighbours of each vertex $v$ receive the same colour as $v$. So one might hope that there is enough slack to prove that for every vertex $v$, at most half the out-neighbours of $v$ receive the same colour as $v$. Section 2 proves Conjecture 2 for digraphs with very large minimum out-degree (at least logarithmic in the number of vertcies), and then for digraphs with large minimum out-degree (at least a constant) and not extremely large maximum indegree. Section 3 shows that large minimum out-degree (at least a constant) is sufficient to prove the existence of one of the colour classes in Conjecture 2. Section 4 discusses multi-colour generalisations of Conjecture 2 .

Before proceeding, we mention some related topics in the literature:

- For undirected graphs, the situation is much simpler. Lovász [7] proved that for every undirected graph $G$ and integer $k \geqslant 1$, there is a $k$-colouring of $G$ such that every vertex $v$ has at most $\frac{1}{k} \operatorname{deg}(v)$ neighbours receiving the same colour as $v$. The proof is simple. Consider a $k$-colouring of $G$ that minimises the number of monochromatic edges. Suppose that some vertex $v$ coloured $i$ has greater than $\frac{1}{k} \operatorname{deg}(v)$ neighbours coloured $i$. Thus less than $\frac{k-1}{k} \operatorname{deg}(v)$ neighbours of $v$ are not coloured $i$, and less than $\frac{1}{k} \operatorname{deg}(v)$ neighbours of $v$ receive some colour $j \neq i$. Thus,
if $v$ is recoloured $j$, then the number of monochromatic edges decreases. Hence no vertex $v$ has greater than $\frac{1}{k} \operatorname{deg}(v)$ neighbours with the same colour as $v$.
- Seymour [9] considered digraph colourings such that every non-sink vertex receives a colour different from some outneighbour, and proved that a strongly-connected digraph $G$ admits a 2 -colouring with this property if and only if $G$ has an even directed cycle. The proof shows that every digraph has such a 3 -colouring, which we repeat here: We may assume that $G$ is strongly connected. In particular, there are no sink vertices. Choose a maximal set $X$ of vertices such that $G[X]$ admits a 3 -colouring where every vertex has a colour different from some outneighbour. Since any directed cycle admits such a colouring, $X \neq \emptyset$. If $X \neq V(G)$, then choose an edge $u v$ entering $X$ and colour $u$ different from the colour of $v$, contradicting the maximality of $X$. So $X=V(G)$. (The same proof shows two colours suffice if you start with an even cycle.)
- Alon [1, 2] posed the following problem: Is there a constant $c$ such that every digraph with minimum out-degree at least $c$ can be vertex-partitioned into two induced digraphs, one with minimum out-degree at least 2 , and the other with minimum out-degree at least 1 ?
- Wood [11] proved the following edge-colouring variant of majority colourings: For every digraph $G$ and integer $k \geqslant 2$, there is a partition of $E(G)$ into $k$ acyclic subgraphs such that each vertex $v$ of $G$ has out-degree at most $\left\lceil\frac{\mathrm{deg}^{+}(v)}{k-1}\right\rceil$ in each subgraph. The bound $\left\lceil\frac{\operatorname{deg}^{+}(v)}{k-1}\right\rceil$ is best possible, since in each acyclic subgraph at least one vertex has out-degree 0 .

## 2 Large Outdegree

We now show that minimum out-degree at least logarithmic in the number of vertices is sufficient to guarantee a majority 3 -colouring. All logarithms are natural.

Theorem 3. Every n-vertex graph $G$ with minimum out-degree $\delta>72 \log (3 n)$ has a majority 3-colouring. Moreover, at most half the out-neighbours of each vertex receive the same colour.

Proof. Randomly and independently colour each vertex of $G$ with one of three colours $\{1,2,3\}$. Consider a vertex $v$ with out-degree $d_{v}$. Let $X(v, c)$ be the random variable that counts the number of out-neighbours of $v$ coloured $c$. Of course, $\mathbf{E}(X(v, c))=d_{v} / 3$. Let $A(v, c)$ be the event that $X(v, c)>d_{v} / 2$. Note that $X(v, c)$ is determined by $d_{v}$ independent trials and changing the outcome of any one trial changes $X(v, c)$ by at most 1 .

By the simple concentration bound ${ }^{1}$,

$$
\mathbf{P}(A(v, c)) \leqslant \exp \left(-\left(d_{v} / 6\right)^{2} / 2 d_{v}\right)=\exp \left(-d_{v} / 72\right) \leqslant \exp (-\delta / 72)
$$

The expected number of events $A(v, c)$ that hold is

$$
\sum_{v \in V(G)} \sum_{c \in\{1,2,3\}} \mathbf{P}(A(v, c)) \leqslant 3 n \exp (-\delta / 72)<1,
$$

where the last inequality holds since $\delta>72 \log (3 n)$. Thus there exist colour choices such that no event $A(v, c)$ holds. That is, a majority 3 -colouring exists.

The following result shows that large out-degree (at least a constant) and not extremely large in-degree is sufficient to guarantee a majority 3 -colouring.

Theorem 4. Every digraph $G$ with minimum out-degree $\delta \geqslant 1200$ and maximum indegree at most $\exp (\delta / 72) / 12 \delta$ has a majority 3-colouring. Moreover, at most half the out-neighbours of each vertex receive the same colour.

Proof. We assume $\delta \geqslant 1200$, as otherwise the minimum out-degree $\delta$ is greater than the maximum in-degree $\exp (\delta / 72) / 12 \delta$, which does not make sense.

We use the following weighted version of the Local Lemma $[4,8]$ : Let $\mathcal{A}:=\left\{A_{1}, \ldots, A_{n}\right\}$ be a set of 'bad' events, such that each $A_{i}$ is mutually independent of $\mathcal{A} \backslash\left(D_{i} \cup\left\{A_{i}\right\}\right)$, for some subset $D_{i} \subseteq A$. Assume there are numbers $t_{1}, \ldots, t_{n} \geqslant 1$ and a real number $p \in\left[0, \frac{1}{4}\right]$ such that for $1 \leqslant i \leqslant n$,

$$
\text { (a) } \mathbf{P}\left(A_{i}\right) \leqslant p^{t_{i}} \quad \text { and } \quad(b) \sum_{A_{j} \in \mathcal{D}_{i}}(2 p)^{t_{j}} \leqslant t_{i} / 2 .
$$

Then with positive probability no event $A_{i}$ occurs.
Define $p:=\exp (-\delta / 72)$. Since $\delta \geqslant 1200$ we have $p \in\left[0, \frac{1}{4}\right]$. Randomly and independently colour each vertex of $G$ with one of three colours $\{1,2,3\}$. Consider a vertex $v$ with out-degree $d_{v}$. Let $X(v, c)$ be the random variable that counts the number of out-neighbours of $v$ coloured $c$. Of course, $\mathbf{E}(X(v, c))=d_{v} / 3$. Let $A(v, c)$ be the event that $X(v, c)>d_{v} / 2$. Let $\mathcal{A}:=\{A(v, c): v \in V(G), c \in\{1,2,3\}\}$ be our set of events. Let $t(v, c):=t_{v}:=d_{v} / \delta$ be the associated weight. Then $t_{v} \geqslant 1$. It suffices to prove that conditions (a) and (b) hold.

Note that $X(v, c)$ is determined by $d_{v}$ independent trials and changing the outcome of any one trial changes $X(v, c)$ by at most 1 . By the simple concentration bound,

$$
\mathbf{P}(A(v, c)) \leqslant \exp \left(-\left(d_{v} / 6\right)^{2} / 2 d_{v}\right)=\exp \left(-d_{v} / 72\right)=\exp \left(-\delta t_{v} / 72\right)=p^{t_{v}} .
$$

[^1]Thus condition (a) is satisfied. For each event $A(v, c)$ let $D(v, c)$ be the set of all events $A\left(w, c^{\prime}\right) \in \mathcal{A}$ such that $v$ and $w$ have a common out-neighbour. Then $A(v, c)$ is mutually independent of $\mathcal{A} \backslash(D(v, c) \cup\{A(v, c)\})$. Since $t_{w} \geqslant 1$,

$$
\sum_{A\left(w, c^{\prime}\right) \in D(v, c)}(2 p)^{t_{w}} \leqslant \sum_{A\left(w, c^{\prime}\right) \in D(v, c)}(2 p)^{1}=2 p|D(v, c)| .
$$

Since each out-neighbour of $v$ has in-degree at most $\exp (\delta / 72) / 12 \delta$, we have $|D(v, c)| \leqslant$ $d_{v} \exp (\delta / 72) / 4 \delta$ and

$$
\sum_{A\left(w, c^{\prime}\right) \in D(v, c)}(2 p)^{t_{w}} \leqslant p d_{v} \exp (\delta / 72) / 2 \delta=\exp (-\delta / 72) t_{v} \exp (\delta / 72) / 2=t_{v} / 2
$$

Thus condition (b) is satisfied. By the local lemma, with positive probability, no event $A(v, c)$ occurs. That is, a majority 3 -colouring exists.

Note that the conclusion in Theorems 3 and 4 is stronger than in Conjecture 2. We now show that such a conclusion is impossible (without some extra degree assumption).
Lemma 5. For all integers $k$ and $\delta$, there are infinitely many digraphs $G$ with minimum out-degree $\delta$, such that for every vertex $k$-colouring of $G$, there is a vertex $v$ such that all the out-neighbours of $v$ receive the same colour.
Proof. Start with a digraph $G_{0}$ with at least $k \delta$ vertices and minimum out-degree $\delta$. For each set $S$ of $\delta$ vertices in $G_{0}$, add a new vertex with out-neighbourhood $S$. Let $G$ be the digraph obtained. In every $k$-colouring of $G$, at least $\delta$ vertices in $G_{0}$ receive the same colour, which implies that for some vertex $v \in V(G) \backslash V\left(G_{0}\right)$, all the out-neighbours of $v$ receive the same colour.

## 3 Stable Sets

A set $T$ of vertices in a digraph $G$ is a stable set if for each vertex $v \in T$, at most half the out-neighbours of $v$ are also in $T$. A majority colouring is a partition into stable sets. Of course, if a digraph has a majority 3 -colouring, then it contains a stable set with at least one third of the vertices. The next lemma provides a sufficient condition for the existence of such a set.
Theorem 6. Every n-vertex digraph $G$ with minimum out-degree at least 22 has a stable set with at least $\frac{n}{3}$ vertices.

Theorem 6 is proved via the following more general lemma.
Lemma 7. For $0<\alpha<p<\beta<1$, every digraph $G$ with minimum out-degree at least

$$
\delta:=\left\lceil\frac{(\beta+p) \log \left(\frac{p}{p-\alpha}\right)}{(\beta-p)^{2}}\right\rceil
$$

contains a set $T$ of at least $\alpha n$ vertices, such that $\left|N_{G}^{+}(v) \cap T\right| \leqslant \beta\left|N_{G}^{+}(v)\right|$ for every vertex $v \in T$.

Proof. Let $d_{v}:=\left|N_{G}^{+}(v)\right|$ be the out-degree of each vertex $v$ of $G$. Initialise $S:=\emptyset$. For each vertex $v$ of $G$, add $v$ to $S$ independently and randomly with probability $p$. Let $X_{v}:=\left|N_{G}^{+}(v) \cap S\right|$. Note that $X_{v} \sim \operatorname{Bin}\left(d_{v}, p\right)$ and

$$
\begin{equation*}
\mathbf{P}\left(X_{v}>\beta d_{v}\right)=\sum_{k \geqslant\left\lfloor\beta d_{v}\right\rfloor+1}^{d_{v}}\binom{d_{v}}{k} p^{k}(1-p)^{d_{v}-k} . \tag{1}
\end{equation*}
$$

By the Chernoff bound ${ }^{2}$,

$$
\begin{equation*}
\mathbf{P}\left(X_{v}>\beta d_{v}\right) \leqslant \exp \left(-\frac{(\beta-p)^{2}}{\beta+p} d_{v}\right) \leqslant \exp \left(-\frac{(\beta-p)^{2}}{\beta+p} \delta\right) \leqslant \frac{p-\alpha}{p} \tag{2}
\end{equation*}
$$

where the last inequality follows from the definition of $\delta$. Let $B:=\left\{v \in S: X_{v}>\beta d_{v}\right\}$. Then

$$
\mathbf{E}(|B|)=\sum_{v \in V(G)} \mathbf{P}\left(v \in S \text { and } X_{v}>\beta d_{v}\right) .
$$

Since the events $v \in S$ and $X_{v}>\beta d_{v}$ are independent,

$$
\mathbf{E}(|B|)=\sum_{v \in V(G)} \mathbf{P}(v \in S) \mathbf{P}\left(X_{v}>\beta d_{v}\right)=p \sum_{v \in V(G)} \mathbf{P}\left(X_{v}>\beta d_{v}\right) \leqslant(p-\alpha) n
$$

Let $T:=S \backslash B$. Thus $\left|N_{G}^{+}(v) \cap T\right| \leqslant \beta d_{v}$ for each vertex $v \in T$, as desired. By the linearity of expectation,

$$
\mathbf{E}(|T|)=\mathbf{E}(|S|)-\mathbf{E}(|B|)=p n-\mathbf{E}(|B|) \geqslant \alpha n .
$$

Thus the desired set $T$ exists.
Proof of Theorem 6. The proof follows that of Lemma 7 with one change. Let $\alpha:=\frac{1}{3}$ and $\beta:=\frac{1}{2}$ and $p:=0.38$. Then $\delta=129$. If $22 \leqslant d_{v} \leqslant 128$ then direct calculation of the formula in (1) verifies that $\mathbf{P}\left(X_{v}>\beta d_{v}\right) \leqslant \frac{p-\alpha}{p}$, as in (2). For $d_{v} \geqslant 129$ the Chernoff bound proves (2). The rest of the proof is the same as in Lemma 7 .

Note the following corollary of Lemma 7 obtained with $\alpha=\frac{1}{2}-\epsilon$ and $p=\frac{1}{2}-\frac{\epsilon}{2}$. This says that graphs with large minimum out-degree have a stable set with close to half the vertices.

Proposition 8. For $0<\epsilon<\frac{1}{2}$, every $n$-vertex digraph $G$ with minimum out-degree at least $2 \epsilon^{-2}(2-\epsilon) \log \left(\frac{1-\epsilon}{\epsilon}\right)$ contains a stable set of at least $\left(\frac{1}{2}-\epsilon\right) n$ vertices.

[^2]
## 4 Multi-Colour Generalisation

In the initial version of this paper we suggested the following natural generalisation of Conjecture 2:

Conjecture 9. For $k \geqslant 2$, every digraph has a vertex $(k+1)$-colouring such that for each vertex $v$, at most $\frac{1}{k} \operatorname{deg}^{+}(v)$ out-neighbours of $v$ receive the same colour as $v$.

Gregory Gauthier [personal communication, Banff workshop "New Trends in Graph Coloring", October 2016] and independently Girão et al. [5] observed that this conjecture is false, as shown by the cyclic orientation of $K_{2 c-1}$, which has out-degree $c-1$ at every vertex, and thus all vertices receive distinct colors. Because of this example, we wonder if Conjecture 9 holds if every vertex has out-degree at least $c$, which is a natural assumption in this context. Without this extra assumption, the following conjecture would be best possible by the above example.

Conjecture 10. For $k \geqslant 2$, every digraph has a vertex $(2 k-1)$-colouring such that for each vertex $v$, at most $\frac{1}{k} \operatorname{deg}^{+}(v)$ out-neighbours of $v$ receive the same colour as $v$.

This conjecture would be best possible by the above example. The proof of Theorem 1 generalises to give an upper bound of $k^{2}$ on the number of colours in Conjectures 9 and 10 . It is open whether the number of colours is $O(k)$.

Lemma 7 with $\alpha=\frac{1}{k}-\epsilon$ and $\beta=\frac{1}{k}$ and $p=\frac{1}{k}-\frac{\epsilon}{2}$ implies the following 'stable set' version of Conjecture 9 for digraphs with large minimum out-degree.

Proposition 11. For $k \geqslant 2$ and $\epsilon \in\left(0, \frac{1}{k}\right)$, every $n$-vertex digraph $G$ with minimum out-degree at least $2 \epsilon^{-2}\left(\frac{4}{k}-\epsilon\right) \log \left(\frac{2}{\epsilon k}-1\right)$ contains a set $T$ of at least $\left(\frac{1}{k}-\epsilon\right) n$ vertices, such that for every vertex $v \in T$, at most $\frac{1}{k} \operatorname{deg}^{+}(v)$ out-neighbours of $v$ are also in $T$.

## 5 Open Problems

In addition to resolving Conjecture 2, the following open problems arise from this paper:

1. Is there a constant $\beta<1$ for which every digraph has a 3 -colouring, such that for every vertex $v$, at most $\beta \operatorname{deg}^{+}(v)$ out-neighbours receive the same colour as $v$ ?
2. Does every tournament have a majority 3 -colouring?
3. Does every Eulerian digraph have a majority 3-colouring? Note that for an Eulerian digraph $G$, if each vertex $v$ has in-degree and out-degree $\operatorname{deg}(v)$, then by the result for undirected graphs mentioned in Section 1, the underlying undirected graph of $G$ has a 4 -colouring such that each vertex $v$ has at $\operatorname{most} \frac{1}{2} \operatorname{deg}(v)$ in- or- out-neighbours with the same colour as $v$. In particular, $G$ has a majority 4 -colouring. By an analogous argument every Eulerian digraph has a 3 -colouring such that each vertex $v$ has at most $\frac{2}{3} \operatorname{deg}(v)$ in- or- out-neighbours with the same colour as $v$, thus proving a special case of the first question above.
4. Does every digraph in which every vertex has in-degree and out-degree $k$ have a majority 3-colouring? A variant of Theorem 4 proves this result for $k \geqslant 144$.
5. Is there a characterisation of digraphs that have a majority 2-colouring (or a polynomial time algorithm to recognise such digraphs)?
6. Does every digraph have a $O(k)$-colouring such that for each vertex $v$, at most $\frac{1}{k} \operatorname{deg}^{+}(v)$ out-neighbours receive the same colour as $v$ (for all $k \geqslant 2$ )?
7. A digraph $G$ is majority c-choosable if for every function $L: V(G) \rightarrow \mathbb{Z}$ with $|L(v)| \geqslant c$ for each vertex $v \in V(G)$, there is a majority colouring of $G$ with each vertex $v$ coloured from $L(v)$. Is every digraph majority $c$-choosable for some constant $c$ ? The proof of Theorem 1 shows that acyclic digraphs are majority 2-choosable, and obviously Theorem 3 and Theorem 4 extend to the setting of choosability.
8. Consider the following fractional setting. Let $S(G)$ be the set of all stable sets of a digraph $G$. Let $S(G, v)$ be the set of all stable sets containing $v$. A fractional majority colouring is a function that assigns each stable set $T \in S(G)$ a weight $x_{T} \geqslant 0$ such that $\sum_{T \in S(G, v)} x_{T} \geqslant 1$ for each vertex $v$ of $G$. What is the minimum number $k$ such that every digraph $G$ has a fractional majority colouring with total weight $\sum_{T \in S(G)} x_{T} \leqslant k$ ?

## 6 Update

Since this paper was submitted there has been significant progress on several of the above open problems.

Question 1 was answered by Anholcer et al. [3] with $\beta=\frac{2}{3}$. More generally, Girão et al. [5] and Knox and Šámal [6] proved that for $k \geqslant 2$ every digraph has a $k$-colouring such that for each vertex $v$, at most $\frac{2}{k} \operatorname{deg}^{+}(v)$ out-neighbours of $v$ receive the same colour as $v$. This answers Question 6 and answers Question 1 with $\beta=\frac{2}{3}$.

Question 2 was partially answered by Girão et al. [5]. They proved that every tournament with minimum out-degree at least 50 is majority 3 -colourable, and that every tournament can be 3 -coloured so that all but at most 7 vertices receive the same colour as at most half of their out-neighbours.

Question 7 was answered by Anholcer et al. [3], Girão et al. [5] and Knox and Šámal [6] who all proved that every digraph is majority 4 -choosable. Moreover, the above results concerning Questions 1 and 6 were established in the choosability setting.

[^1]:    ${ }^{1}$ The simple concentration bound says that if $X$ is a random variable determined by $d$ independent trials, such that changing the outcome of any one trial can affect $X$ by at most $c$, then $\mathbf{P}(X>\mathbf{E}(X)+t) \leqslant$ $\exp \left(-t^{2} / 2 c^{2} d\right)$; see [8, Chapter 10]. With $\mathbf{E}\left(X_{v}\right)=d_{v} / 3$ and $t=d_{v} / 6$ and $c=1$ we obtain the desired upper bound on $\mathbf{P}\left(X_{v}>d_{v} / 2\right)$.

[^2]:    ${ }^{2}$ The Chernoff bound implies that if $X \sim \operatorname{Bin}(d, p)$ then $\mathbf{P}(X \geqslant(1+\epsilon) p d) \leqslant \exp \left(-\frac{\epsilon^{2}}{2+\epsilon} p d\right)$ for $\epsilon \geqslant 0$. With $\epsilon=\frac{\beta}{p}-1$ we have $\mathbf{P}(X>\beta d) \leqslant \exp \left(-\frac{(\beta-p)^{2}}{p+\beta} d\right)$.
